

# First Report of Pedestrian Counting

Wang Zhengrong, Hsienyu Meng, Liuyang Zhan

April 15, 2015

## 1. Introduction

Pedestrian detection and counting has been heavily researched in the last few years and people have made great improvement. Dalal's HoG (Histogram of Gradients) operator has been widely used in pedestrian detection with SVM, AdaBoost or other machine learning algorithms, which we use as the basic detector in our project.

However, detection is not enough to count the pedestrians in the ROI, therefore we have to track each person. Our basic idea is to use particle filter to track each specific person.

Particle filter is an approximation of Bayes inference and is widely used in tracking. Compared with Kalman filter, it can simulate any probability distribution. However its main drawback is the high complexity of computation. Which we will try to optimize with multiple threads.

## 2. Basic Plan

Here is our basic plan for this project.

- Code Reconstruction

The code offered by the teacher is not object-oriented, and is very difficult to modify and extend. Hence our first goal is to reconstruct the program so that we can easily build our particle filter on it.

Besides, while reconstructing the program, we rewrite some parts of the program in a more memory friendly way, which leads to quite tremendous improvement. The original video detector on the first training video takes 212s, while our reconstructed program takes 66s with one main thread. After optimizing some parameters it reduces to 27s without deteriorating its precision.

- Merge Particle Filter

The main idea is from [1], in which there are mainly two new ideas. The first one is that instead of using one offline trained general classifier, they train one online classifier for each detected pedestrian and the classifier is only updated on non-overlapping detections. Secondly, the detections are used to guide the particles' propagation which is implemented to estimate the conditional likelihood of the new observation.

- Data Association Problem

The data association problem is solved by a greedy algorithm. A matching score is calculated for each pair of detection and pedestrian, then we selected the max matching score and delete the corresponding row and column of this pair. Last, only matching pairs that above some threshold is used to guide the particles of that pedestrian.

- Online Boosting

The online boosting classifier for each pedestrian is similar to that in [2] and we will select some features to train it.

- Optimization

With multiple threads or even GPU programming, we may achieve the real time interactive result.
